Abstract

This paper describes the implementation of an interface which allows runtime queries from a PATR-II grammar to a precompiled DATR lexicon during the parse of a sentence. The lexical information requested by the PATR system is then unified to the PATR parse tree. Alternatively, there is the option to create all the possible dictionary entries from a DATR lexicon before parsing starts; these entries are stored in a file and can be loaded together with a PATR-II grammar.

The main advantages of this interface are firstly, that it allows the grammar writer to make use of the powerful multiple and default inheritance mechanism (with the possibility of overriding defaults) which DATR provides — and therefore to be able to exploit all the redundancies — and secondly, that the lexical information stored as a DATR theory can be accessed at runtime of the parser, if and only if it is needed.

B Sample (demo) run of the system 44
0 Introduction

Despite the fact that one of the purposes of the DATR formalism is to provide a system which is

intended to be complementary to ... PATR (Gazdar (1989: 11)),

and which

has the necessary expressive power to encode the lexical entries presupposed by contemporary work in the unification grammar tradition (Gazdar (1989: 1)),

there have not been many noticeable approaches so far which deal with the issue of interfacing DATR and PATR in order to get a combined system, maximally benefitting from the advantages of both of its components.

PATR\(^1\) is a unification based grammar formalism where lexical information can be included (and usually, this is in fact the case) but cannot be handled very economically; the only option here is to use macros (templates) to simplify the lexicon definition. However, if one uses a DATR theory for encoding lexical information, one can exploit all the features of a powerful multiple default inheritance mechanism, where regularities, subregularities and idiosyncrasies can easily be captured.

The ideal solution, then, would be to separate the grammar and the lexicon: to write the grammar using the PATR formalism and to encode all the lexical information (morphological, syntactic, semantic) in DATR; and whenever the parser needs the information from the lexicon, it accesses DATR directly to obtain it.

We shall see, that for some reasons, the approach pursued here is slightly different but comes quite close to this ideal goal.

1 Representation of lexical information in a PATR system

1.1 The syntax of lexical entries

When we use a PATR system for encoding both grammar and lexicon, a typical lexical entry would look like that:

\[
\text{dict(plays, x0[ x/syn/cat} \Rightarrow v, \\
x/syn/subcat/first/syn/cat} \Rightarrow \text{np,} \\
x/syn/subcat/rest} \Rightarrow \text{nil,} \\
x/mor/num} \Rightarrow \text{sing,}
\]

\(^{1}\)Throughout this paper I will refer to the following implementations of PATR resp. DATR: the Edinburgh Sictus-Prolog PATR-II system by A.Schoeter and the Sussex Prolog DATR system by R.Evans et al. (Version 2.00). The general discussion in this paper, however, will also apply for any other implementations of PATR or DATR.
\[ X/\text{mor/pers} \leftrightarrow 3, \]
\[ X/\text{sem/name} \leftrightarrow \text{play}, \]
\[ X/\text{sem/type} \leftrightarrow \text{activity}, \]
\[ X/\text{syn/subcat/first/sem} \leftrightarrow X/\text{sem/arg}]. \]

I.e., we have a Prolog clause, \texttt{dict/2}, which is called by the parser whenever it reads the next token (word) from the input string (and, of course, during backtracking as well). The first argument of \texttt{dict/2} has to match this word, the second argument returns all the unified attribute–value pairs in square brackets; these path equations are evaluated and "attached" to the tree variable \( X \) which forms the second argument of the \texttt{dict/2} predicate.

In principle, the path equations can have two forms:

(a) \[ X/\text{attr1}/.../\text{attrM} \leftrightarrow \text{value} \]

where an atomic value is assigned to a path; or

(b) \[ X/\text{attr11}/.../\text{attr1N} \leftrightarrow X/\text{attr21}/.../\text{attr2M} \]

where the values of two distinct paths are unified.

1.2 Handling of morphological ambiguities

Consider the verb \texttt{TO PLAY} whose present tense active paradigm has six elements (two numbers times three persons) but only two morphologically distinct forms (\texttt{plays} for third person singular and \texttt{play} elsewhere). There are two alternative ways of defining lexical entries in a PATR system: Either, one defines just two lexical entries for these two forms and ignores the number and person features in the \texttt{play} entry; in this case one has to face the problem of over-generation because the parser will not reject sentences like: \textit{The boy play the violin}. Or, on the other hand, one explicitly encodes all the six number–person combinations, in which case, of course, the lexicon will get quite large if it consists of a lot of lexemes like that.

In the next section, we will see how this issue can be handled via the DATR formalism in a much more elegant way.

2 Representation and retrieval of lexical information in DATR

2.1 General properties of the DATR formalism

Though DATR can be used for a whole variety of things (see e.g. the examples in Evans \& Gazdar (1990)), its main purpose is to be

a formal language which is intended to facilitate the representation of lexical information. The goal ... has been to design and implement a simple language that (i) has the necessary expressive power to encode the lexical entries presupposed
by contemporary work in the unification grammar tradition, (ii) can express all
the evident generalisations about the information explicit in those entries, (iii) has
an explicit theory of inference, (iv) is computationally tractable and (v) has an
explicit declarative semantics. DATR defines networks allowing multiple default
inheritance of information through links typed by attribute paths. ... DATR has
a set of seven rules of inference, a general principle of default inference, and a
model-theoretic semantics inspired by that developed for auto-epistemic logic.
DATR is functional, that is, it defines a mapping which assigns unique values to
node attribute-path pairs. Recovery of these values is deterministic — no search
is involved.

Linguistically, the language allows a uniform treatment of irregularity, sub-
regularity and regularity and provides a logical basis for theories of suppletion,
syncretism, declension, conjugation, and the paradigm. In addition, it offers an
explicit reconstruction of informal notions such as “blocking”, the “elsewhere con-
dition”, and the “proper inclusion precedence” principle. (Gazdar (1989: 1))

2.2 Representation of lexical information in DATR

The way information is stored in a DATR theory is very straightforward. In principle, one
has to distinguish between nodes, paths and values. The nodes can be seen as the entry
points to the DATR network, the paths can be interpreted as links (respectively, as a list of
links) which either point to other nodes, other paths or directly to a (definite) value.

I will not expand on the syntax and semantics of DATR here because this was done extensively
in several papers in Evans & Gazdar (1990) and e.g. also in Erjavec (1992). I will just illustrate,
how the above discussed example of storing morphologically ambiguous words can be handled
within the DATR formalism (this example is taken out from the file music2.dat):

WORD:     ≤ = unspecified
        <mor num $num pers $pers> = "<mor $num $pers>"
        <path1 gapin path2 gapout> = path_unify.

VERB:      ≤ = WORD
        <syn cat> = v
        <mor sing 1> = "<root>"
        <mor sing 2> = "<root>"
        <mor sing 3> = (<"root"> s)
        <mor plur 1> = "<root>"
        <mor plur 2> = "<root>"
        <mor plur 3> = "<root>".

VERB_NPCOMP: ≤ = VERB
        <syn subcat first syn cat> = np
        <syn subcat rest> = nil.

PLAY_V:    ≤ = VERB_NPCOMP
        <root> = play.
In this example one can see several of the interesting features of the DATR language:

- The entry for the lexeme `PLAY , V` contains just two DATR equations though it comprises information about all its six forms.

- The `default` is indicated in the first line: it points to the node `VERB: INCOMP` and there further on to the node `VERB`, where the conjugation of the relevant group of verbs is given.

- But even there, we have a reference to the global node `WORD`, where the general rules holding for all words in the lexicon are specified.

- At the more general nodes, the item `"<root>"` refers to the respective value of the `<root>`-path in the node for which a query is performed. That means in the case of this example, that the morpheme `-s` will get appended to the stem `play` (in the third person singular form).

- The first line of the `WORD` node states that all paths where no values can be found are unspecified (by default).

- The second line expands paths of the form e.g. `<mor sing 1>` to `<mor num sing pers 1>`. The reason for this is explained in section 4.

- The third line gives an example for a path unification declaration in DATR (see example (b) in section 1.1). We have developed a specific syntax for this purpose which uses reserved words. This will be explained later on, as well.

2.3 Querying DATR

Using the DATR language can be seen as a way of representing a formal theory. The queries, then, can be interpreted as theorems of the theory. The actual DATR system is designed as a deterministic one, i.e. the user has to question the system in a way that it can access the information without the need of backtracking.

As a consequence of this requirement, the DATR query has the form:

\[
\text{datr_query}(@\text{Node}, \text{?Path}, \text{?Value})
\]

where the node has to be specified and both the path and value parameters can either be specified (i.e. be a non-variable argument) or left unspecified, in which case DATR just returns the first solution it can find.

In the first Sussex DATR implementation, there were only limited possibilities of querying DATR. However, in the improved version 2.0, described in Jenkins (1990), there are ways of

- specifying those nodes that are not "relevant" for user queries

- specifying those paths that shall be shown in a "general" query (we will call these specifications now `relevant information`), and
• querying all this relevant information from either one node or all the relevant nodes (predicate: datr:theorem)

With these extensions, the possibilities of querying DATR have been significantly increased and we shall see in the following sections how these runtime improvements can help a great deal in the implementation of the DATR–PATR interface.

3 DATR–PATR interfaces and the reverse query problem

3.1 General issues and problems

Accessing lexical information from a DATR theory would be very easy and straightforward if there were a 1:1-correspondence between a word form in the dictionary and a node in the DATR theory. While this may be possible in isolating, non-inflectional languages like Chinese, this is quite different for most of the European languages, such as German, French and even English: here we typically have morphological paradigms for verbs, nouns and adjectives. That is, we want to generalise over different classes of declensions and conjugations and derive all morphological forms of one lexeme at one node via the inheritance mechanism of DATR (see the above example in section 2.2).

If the parser encounters an inflected word form, it has to find out from which node (stem) it was derived in order to get the necessary morphological, syntactic and semantic information it needs.

Let us look at an example in order to clarify matters: Assume the parser’s current token is the word PLAYS. In the DATR theory of the example file music2.dtr there are two possible morphological paths which result in the value list [play,s]:

(a) <mor num plur pers 3>
(b) <mor num sing pers 3>

The first path corresponds to PLAYS as a noun, the second as a verb. In this case, these two paths originate at two different nodes which means that not only this morphological information differs but also the syntactic and semantic information associated with these two lexical entries. (We could call this inter-node ambiguity as opposed to the (more common) intra-node ambiguity which has been discussed in section 1.2).

This example illustrates that we need a mechanism of reverse querying in order to get the lexical information from DATR to the PATR system (or, to be more precise, to the parser which operates on the PATR grammar): As stated above, DATR is designed for querying for values, if the node (and the path) is known in advance. In our case, however, we know the values — to be exact: the concatenation of the value list — but neither the paths nor the nodes. Moreover, we do not only want to get access to the path “pointing” to the value list in question but to all the other relevant paths of the node where the value list “belongs” to, as well. That is, in fact, we need to obtain the syntactic and semantic information together with the morphological one.
3.2 Previous approaches

Kilbury et al. (1991) incorporate the syntactic characters for Prolog lists (brackets, colons, commas) directly in the DATR theory so that the result of a query can be transformed with some quite trivial intermediate steps to a PATR suitable difference list (see Zechner (1995) for a more detailed account on that). However, this idea is on the one hand not very elegant in terms of the DATR encoding and on the other hand it is only useful in a system where the name of the queried node is known in advance; i.e., this approach cannot be taken to solve the reverse query problem.

Zechner (1995) describes an on-line access system where a DATR theory is used to store semantic information which is queried directly via a Prolog predicate from the PATR lexicon. As the nodes are — and have to be — always known at query time, this system cannot be employed for reverse queries either.

Langer (1994) explicitly addresses the reverse query issue and provides an algorithm for a bottom-up chart parser which is able to retrieve all the possible node-path pairs\(^2\) in a DATR theory with a value list as input query.\(^3\) The problems with this approach for our DATR-PATR interface are however, that on the one hand, it requires a “split” list of values as a query (e.g. [play\(_s\)] for the word \textsc{plays}) — which is not what we have got when the parser encounters an inflected word — and, on the other hand, only returns the nodes together with the “direct” morphological paths “pointing” to the value list of the query.

The next section describes a system which is capable of solving these problems in an elegant and efficient way.

4 Description of an efficient and general DATR–PATR interface

4.1 Creating the dictionary “on the fly”

The first problem our system\(^4\) has to solve is the morpheme concatenation problem. It seems as if this were a superficial matter but, as we already have seen, it is not at all. Even if we take a reverse query approach like the one described in Langer (1994) there is no way for DATR in finding out which value list corresponds to an atomic (inflected) word form.

Therefore, I decided to precompile the DATR theory in a format which has the atomic, inflected forms as values instead of value lists. The format of these npv/3 predicates (for: NODE–PATH–VALUE) is illustrated in the following example, where all the npv/3 facts for both the verbal and the nominal node of \textsc{play} are listed:\(^5\)

\(^2\)The length of the paths has to be set to a predefined limit for computational reasons.

\(^3\)Langer has implemented this algorithm in Arity Prolog.

\(^4\)The description here is a very general one; for a more detailed account you have to look at the well-commented source code in the appendix. (See the file README for a description of the usage of the system.)

\(^5\)These npv/3 facts are built using the runtime improvements of the Sussex Prolog DATR implementation, Version 2.00, described in Jenkins (1990). Specifically, this procedure heavily relies on the notion of \textit{relevant information}, explained in section 2.2; i.e., only those nodes are considered which are not “hidden” (\#hide) and those paths which are to be “shown” (\#show).
\texttt{npv('PLAY\_V', [syn,cat], v)}.
\texttt{npv('PLAY\_V', [syn,subcat,first,syn,cat], np)}.
\texttt{npv('PLAY\_V', [syn,subcat,rest], nil)}.
\texttt{npv('PLAY\_V', [mor, num, sing, pers, 1], play)}.
\texttt{npv('PLAY\_V', [mor, num, sing, pers, 2], play)}.
\texttt{npv('PLAY\_V', [mor, num, sing, pers, 3], plays)}.
\texttt{npv('PLAY\_V', [mor, num, plur, pers, 1], play)}.
\texttt{npv('PLAY\_V', [mor, num, plur, pers, 2], play)}.
\texttt{npv('PLAY\_V', [mor, num, plur, pers, 3], play)}.
\texttt{npv('PLAY\_V', [path1, gapin, path2, gapout], path_unify)}.
\texttt{npv('PLAY\_N', [syn, cat], n)}.
\texttt{npv('PLAY\_N', [mor, num, sing, pers, 3], play)}.
\texttt{npv('PLAY\_N', [mor, num, plur, pers, 3], plays)}.
\texttt{npv('PLAY\_N', [path1, gapin, path2, gapout], path_unify)}.

There are a couple of other advantages which you get for free when using this method:

- you can leave out all the paths which have no specified value (keyword: \texttt{unspecified}) and get a compact DATR lexicon containing only the information you want to provide for a query from the PATR system

- you need not use the DATR system and its evaluation predicates \textit{at all} while running the PATR system; this saves time and memory

- before starting the parser, you need not load the DATR system and the relevant DATR theories because all the interface system \textit{is} looking for are the \texttt{npv/3} facts which contain all the necessary information of the respective DATR theory

The second problem is to create a dictionary entry (predicate \texttt{dict/2}) which contains exactly the amount of lexical information we want to have, i.e., from a given node–word pair: the syntactic, semantic and morphological information. Moreover, our system also has to handle path equations of the form discussed in example (b) in section 1.1 which fall in neither of these categories of information.

The solution I take is to collect \textit{all} the information stored in a node into a list (via the standard predicate \texttt{bagof}) and then separate this list into three pieces (predicate \texttt{separate_list} in the file \texttt{queries2.pl}):

1. the morphological information corresponding to the lexical entry

2. the syntactic and semantic information

3. the path–pairs which have to be unified

After the syntactic and semantic information (2) have been assigned to a PATR tree variable and the path–pairs (3) have been unified, an “intermediate tree” is created (dynamically asserted to the Prolog database) which serves as a basis for the generation of all \texttt{dict/2} entries which have identical morphological forms but distinct morphological paths (1) (all
this applies for one single node; if the same word form occurs at more than one node, the whole procedure is repeated accordingly).

In the following example, we see all the npv/3 facts for the word form PLAY and afterwards the dict/2 entries which the interface system creates if queried with this word form:

npv('PLAY_V', [mor, num, sing, pers, 1], play).
npv('PLAY_V', [mor, num, sing, pers, 2], play).
npv('PLAY_V', [mor, num, plur, pers, 1], play).
npv('PLAY_V', [mor, num, plur, pers, 2], play).
npv('PLAY_V', [mor, num, plur, pers, 3], play).
npv('PLAY_N', [mor, num, sing, pers, 3], play).

Remark 1: The system uses the following reserved words (to be encoded in the DATR theory):

- **unspecified**: value which is not specified (this will not be included in the list of npv/3 facts)
- **path1, path2**: path-delimiters for path unification purposes
- **path unify**: dummy value for path unification purposes
- **mor**: header for morphological paths

Remark 2: The morphological paths consist of the header (mor) and a sequence of attribute-value pairs. (This was done for simplicity of the algorithm which constructs the morphological information for the PATR tree. In principle, one could easily extend the system to more complex morphological paths.)

The dict/2 predicates are dynamically asserted to the Prolog database so that all of them are available to the parser for backtracking or subsequent queries.
These interface procedures are triggered whenever the PATR system does not find a relevant \texttt{dict/2} entry in the database and therefore has to employ the generic entry (calling the query predicate) which looks like that:

\begin{verbatim}
dict( Word, Tree@[d2p_query(Tree, Word)] ) .
\end{verbatim}

If the parser reaches this generic entry \textit{although} the current word has already been queried, then this means that all possibilities of the current lexical item have been checked without success and the parser has to backtrack to previous choice points (predicate \texttt{check_prev_query} in the file \texttt{queries2.pl}).

To summarise: In this variant of the system, whenever the parser does not find a word in the (dynamic) \texttt{dict/2} database, it executes a query to the precompiled \texttt{npv/3} lexicon and in the course of this, all relevant \texttt{dict/2} entries are created and asserted to the Prolog database. (Initially, there is \textit{only} the generic \texttt{dict/2} entry in the database (included in the PATR file).)

\subsection{4.2 Using a precompiled dictionary in PATR format}

An alternative variant of our system, which saves time but (generally) consumes more memory, is to create all the possible \texttt{dict/2} entries from the \texttt{npv/3} facts beforehand and to use them directly, quasi as a PATR style lexicon. Of course, here you will find no elimination of redundancies whatsoever but the point is to use a DATR theory as a basic, elegant pattern for the representation of the lexicon and to do the compilation to form the PATR \texttt{dict/2} entries just before you use the PATR grammar and parser.

In this variant, there is no generic \texttt{dict/2} entry because there is no need to construct (new) \texttt{dict/2} entries any more.

\subsection{4.3 Various useful predicates of the system}

The most important predicate is \texttt{d2p_query/2} in the file \texttt{queries2.pl} which (together with its subpredicates) does all the work of creating \texttt{dict/2} entries from the \texttt{npv/3} predicates. In the file \texttt{misc2.pl}, there are predicates for

\begin{itemize}
\item performing a demo run (\texttt{showdemo})
\item parsing sentences (\texttt{mparse})
\item precompiling a DATR theory (\texttt{datr2db})
\item reading or writing \texttt{npv/3} facts from/to a file (\texttt{readdatr.db}, \texttt{datr2file})
\item reading or writing \texttt{dict/2} entries from/to a file (\texttt{readdict.db}, \texttt{dicts_to_file})
\item switching from "dict"-mode to "npv"-mode (\texttt{npv_mode})
\end{itemize}
5 Summary and outlook

In this paper, I have discussed an implementation of an interface system which allows a runtime access from a PATR grammar/parser to a precompiled DATR lexicon. The system operates either on a DATR style representation or on a full-fledged PATR suitable dictionary compiled from a DATR theory.

Investigations concerning the time and space complexity of this system and for other recently proposed approaches (theoretically as well as with examples of a realistic size) still remain to be issues of future research.

music2.dtr   : DATR-lexicon for music instruments plus additional
               lexical entries of several categories

m_gram2      : PATR-grammar which does on-line calls to DATR
               (resp. to a database of precompiled clauses or
               to a precompiled dictionary)

m_gram2.links: link information, built from m_gram2

queries2.pl  : the DATR->PATR query predicate

m_misc2.pl   : predicates for the demo, file-io,
               the call for the parser and other stuff

music_init.pl: initialization-module

m_demo2      : demo-file with sample sentences

c12tp.tex    : LaTeX source code of term paper (contains a
               more extensive documentation section)

datr_init.pl : initialization of DATR (which is not necessary
               for a standard run of the system for the queries
               either go to a precompiled set of npv/3 clauses
               or a precompiled set of dict/2 clauses is used)
music2.npv : precompiled npv/3-clauses (info from DATR about
node-path-value triples, used file music2.dtr)

music2.dict : precompiled dict/2-clauses (from DATR file
music2.dtr; can be consulted as a lexicon for
a PATR grammar; it has the suitable format)

Usage of the System:
************************

At the PROLOG-prompt, just type:

| ?= [music_init].

... and after a while, all the files will have been loaded and
you will be given an information how to start a small demo, i.e.
typing:

| ?= show_demo.

After having seen these examples you can write your own sentences
using the predicate m_parse:

| ?= m_parse.

... or you can switch to the off-line mode which is a bit faster
(it uses a precompiled dictionary) but (possibly) consumes more
memory:

| ?= read_dict_db('music2.dict').

(Type y and RETURN when asked to redefine the dict/2 predicate.)

In order to switch back to on-line mode (which creates all dict/2
entries during runtime of the parser as needed), type:

| ?= npv_mode('music2.npv').

List of Words in the DATR-lexicon:
*******************************
determiners:
a, the
nouns:
  violin, viola, cello, contrabass (sing/plur)
  contrabass_1948b, contrabass_1909a,
guarnieri_1679a, stradivari_1657b (sing)
  lb_3500, lb_20000 (plur)
  play (sing/plur) (n/v ambiguity)

pp’s:
  under_chin, on_ground

verbs:
  cost [subcat n]
  is_played [subcat pp]
  play [subcat np] (n/v ambiguity)

pronouns:
  i, you, it, we, they

date: May 2013

desc: A table of words with senses.

example sentences:
  a play costs lb_3500.
  the stradivari_1657b costs lb_20000.
  the contrabass_1909a is_played on_ground.
  the contrabasses cost lb_3500.
  i play the violin.

% % file: m_gram2:a small PATR-II grammar for accessing DATR in %
% the music-example (music2.dtr) % %
% % %%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%

% This grammar just allows the parsing of very simple declarative % sentences. The point of it, however, is to demonstrate the use % of the DATR-PATR-interface, which in this example queries the % lexical information from DATR for all occurring words in % the parse and stores it in the resulting PATR-tree (the lexical % information is stored in the database, npv/3-facts).
%
% note: for example sentences see file README (or the term paper)
%
% dict/2 has to be dynamic; at each query, the relevant % dict-entries are added to the database (if not there):
:- dynamic dict/2.
%
% grammar:
%
% rules : s -> np vp
%   vp -> v [subcat]
%   np -> det n
%   np -> pron
%
% note: three types of information is passed on:
% syn : syntactic structure
% sem : semantics
% mor : morphology (the resulting mor-info
% at the s node represents the projection
% of the verbal head)

X0 ---> [X1,X2]@[X0/syn/cat <=> s,
